hukaiwen@shpingheschool.com*

Abstract. Depression is a highly heterogeneous neuropsychiatric disorder. The poor therapeutic efficacy, limited treatments, and persistently high relapse rates underscore the urgent need to explore new therapeutic methods. Growing evidence shows that inflammation in the brain plays a vital role in depression. Current treatments for depression tend to overlook this diet-inflammation link. This study examines the genomic and transcriptomic patterns of brain inflammation induced by high-fat diets(HFD). Based on high-throughput sequencing data from the GEO database, we revealed the transcriptional characteristics of neuroimmune imbalance in depression through differential expression analysis, GO, KEGG, and other analyses. We screened for Medicine-Food Homology (MFH) with potential antidepressant effects by integrating multi-omics analysis with network pharmacology. We found that an HFD induces alterations in brain gene expression and affects the process or biological function of monoamine neurotransmitter transport. We identified six MFH substances with potential therapeutic effects against depression, whose mechanisms may involve modulating the activity of membrane transporters and neural signalling. This work supports the idea that what we eat can profoundly shape brain health. These molecular patterns may provide a new idea of more accurate and personalised treatment for mood disorders related to a high-fat diet, to prevent and treat depression more effectively.

Keywords: Depression, Neuroinflammation, High-fat diet, RNAseq analysis, Network pharmacology, Medicine-Food Homology substances

1. Introduction

Depressive disorder (also known as depression) is a common mental disorder with a depressed mood or loss of pleasure or interest in activities for long periods of time. It involves a depressed mood or loss of pleasure or interest in activities for long periods of time [1]. Depression is a disease which is a highly prevalent and debilitating mental disorder. It is recognized as one of the leading causes of global disease burden. According to the World Health Organization (WHO), major depressive disorder affects approximately 6% of the population annually, with a lifetime prevalence of up to 15-18% [2]. Although nowadays pharmacological and psychological therapies do exist,

current treatments are not universally effective, and relapse rates remain high. This highlights our need to explore novel pathogenic mechanisms and therapeutic [3].

Growing evidence shows that inflammation in the brain, or neuroinflammation, plays a vital role in depression [4]. Diets high in fat or cholesterol are not only linked to metabolic problems but also to anxiety- and depression-like behaviours in both people and animal studies [5,6]. For example, mice fed a high-cholesterol diet (42% kcal fat + 1.25% cholesterol) developed anxiety- and depression-like behaviours accompanied by increased peripheral and central inflammation [7]. Similarly, obese rats on a high-fat diet exhibited elevated pro-inflammatory cytokines in the hippocampus and impaired serotonergic responses to escitalopram [8]. In ageing rats, even short-term high-fat intake led to hippocampal- and amygdala-dependent memory deficits, with increased microglia activation [9]. Notably, hypothalamic inflammation-including microgliosis, astrogliosis, and elevated TNF- α -was observed within 1-3 days of high-fat diet exposure. Recent preliminary analyses using lipidomic and transcriptomic approaches have begun to elucidate how saturated fat disrupts hypothalamic cAMP/PKA signalling via PDE4A activation, linking dietary intake with mood regulation pathways [10].

A high-fat diet (HFD) not only leads to obesity and metabolic syndrome but is also closely related to the occurrence of depression through multiple mechanisms. Long-term HFD can disrupt the intestinal barrier and homeostasis of intestinal flora, increase circulating levels of free fatty acids and inflammatory cytokines, thereby triggering low-grade chronic inflammation (Li., 2025). This peripheral inflammation can cross the blood-brain barrier and enter the central nervous system, activating microglia and astrocytes and inducing neuroinflammatory responses (Ma, 2025a). Meanwhile, abnormal lipid metabolism leads to mitochondrial dysfunction, oxidative stress and lipid droplet deposition, further altering the microglial phenotype and resulting in synaptic damage and impaired neural plasticity (Ma, 2025b). These dual imbalances in neuroimmunology and metabolism cause individuals to exhibit behavioural symptoms such as anxiety, anhedonia and cognitive impairment, forming an essential pathological bridge between obesity, metabolic disorders and depressive symptoms (Ma, 2025a and b). The relationship between obesity and depression is not one-way but rather an interactive and mutually reinforcing process. Under the state of obesity, pro-inflammatory factors (such as IL-6, TNF- α) secreted by excessive adipocytes and reactive oxygen species exacerbate peripheral inflammation through signalling pathways such as NF- κ B, and induce excessive activation of M1-type microglia in the central nervous system, thereby damaging neurons and synaptic connections. Promoting the occurrence of depression [11]. Conversely, Depression can also lead to abnormal appetite and imbalance in energy metabolism through HPA axis disorder and elevated cortisol levels, thereby increasing the risk of obesity (Depression and obesity: evidence of shared)

Over time, such dietary patterns appear to induce inflammation in the hypothalamus, amygdala and hippocampus, which are directly implicated in regulating emotional responses within the brain. This also indicates that our diet directly influences brain health by altering immune pathways.

A study has revealed how diet-induced inflammation contributes to the development of depression [12]. Nevertheless, many questions remain unanswered. For instance, the precise molecular pathways linking high-fat diets to alterations in brain inflammation and depressive symptoms remain unclear.

Current treatments for depression also tend to overlook this diet-inflammation link, leaving a gap between what we know and how we treat patients. To deal with this challenge, this study focuses on the genomic and transcriptomic patterns of brain inflammation induced by a high-fat diet. By integrating multi-omics analysis and network pharmacology, we want to identify potential

therapeutic targets and elucidate how everyday dietary habits may influence the onset and progression of depression. Ultimately, this work may open up new possibilities for more precise and personalised treatments for mood disorders influenced by HFD.

2. Materials and methods

2.1. Raw data source for RNAseq analysis

To identify differentially expressed genes associated with a high-fat diet (HFD), metabolic abnormalities, and depression, we retrieved relevant transcriptome sequencing (RNA-seq) data from the Gene Expression Omnibus (GEO) database (<https://www.ncbi.nlm.nih.gov/geo/>). Finally, the GSE272983 dataset [13] was chosen. In the original study, mice were divided into the Control diet (CD) and the High-fat diet (HFD). Among them, the mice in the CD group received a standard diet throughout the experiment. In contrast, the mice in the HFD group were fed a high-fructose diet for an extended period to induce metabolic syndrome and related neuroinflammatory responses. Based on the experimental design from the original literature, the researchers further evaluated depressive and anxiety-like manifestations at the behavioural level (such as sucrose preference experiments and forced swimming experiments), and combined transcriptome sequencing to reveal the potential molecular mechanisms by which dietary factors influence neuroimmune responses and emotional disorders.

2.2. Differentially expressed gene and enrichment analysis of RNAseq raw data

The gene expression count matrix (GSE272983_countMatrix) was retrieved from the Gene Expression Omnibus (GEO) database (Accession: GSE272983). Differential expression analysis between the CD group and the HFD group under stress conditions was performed using the limma R package. Differentially expressed genes (DEGs) were identified based on the following criteria: adjusted P-value < 0.05 and absolute fold change (FC) \geq 1.5. Volcano plots were generated using the ggplot2 R package to visualize the DEGs.

Functional enrichment analysis of the DEGs was conducted online platform (<https://www.bioinformatics.com.cn/>, accessed on 9 September 2025), including Gene Ontology (GO) analysis across three domains-biological process (BP), molecular function (MF), and cellular component (CC)-as well as KEGG pathway analysis.

2.3. Network pharmacology analysis

The Traditional Chinese Medicine Systems Pharmacology Database and Analysis Platform (TCMSP) (<https://www.tcmsp-e.com/>) and the HERB database (<http://herb.ac.cn/>) were employed to predict the potential targets of these six substances. Screening criteria included an oral bioavailability (OB) value >30% and a drug-likeness (DL) index \geq 0.18. Differentially expressed genes (DEGs) were used as depression-related targets. To identify the potential therapeutic targets of Medicine-Food Homology (MFH) in depression, an intersection analysis was conducted between MFH-related targets and DEGs targets. A Venn diagram was generated using the online platform SRplot (<https://www.bioinformatics.com.cn/>) to visualize the overlapping targets. The STRING online database (<https://cn.string-db.org/>) was utilized to construct and analyze the protein-protein interaction (PPI) network of the overlapping targets between the herbal compounds and depression-related genes. Hub genes were identified from the PPI network and subsequently subjected to Gene

Ontology (GO) enrichment analysis and Kyoto Encyclopedia of Genes and Genomes (KEGG) pathway analysis to explore their biological functions and underlying mechanisms.

3. Results

3.1. Analysis result of differential expression genes

In the original research, the animals in the HFD showed major depressive disorder (MDD) like-phenotype through the forced swim test and tail suspension test following the chronic unpredictable mild stress (CUMS) treatment. And in the Novel Object Recognition Test we found CUMS induced cognitive impairment-like phenotype in mice on HFD [13]. To investigate the role of HFD-related neuroinflammation in the development of depression, this study primarily focused on the differentially expressed genes in the CD group and the HFD group under stress, using these as the basis for subsequent bioinformatics analysis.

First, we found that a HFD caused clear changes in brain gene expression, including 22 genes upregulated, 416 genes downregulated and 55,049 genes showing no significant change (Fig. 1). Next, we performed enrichment analysis on the up- and down-regulated genes among the 438 DEGs, including GO and KEGG pathway analysis.

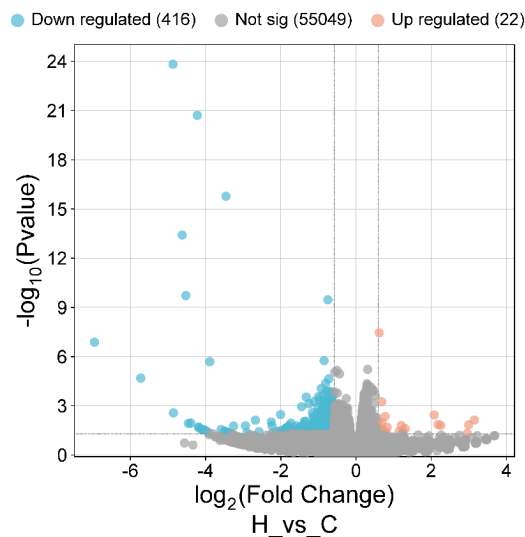

Figure 1. Volcano plots comparing the brain gene expression levels between the HFD group (H) and the CD group (C)

3.2. HFD downregulated the genes involved in neurotransmitter transport and regulation of calcium ion channel activity

GO enrichment analysis of down-regulated genes revealed significant enrichment ($p < 0.05$) in biological processes (BPs), cellular components (CCs), and molecular functions (MFs) (Fig. 2). In terms of biological processes, these genes were primarily enriched in response to lead ion, negative regulation of voltage-gated calcium channel activity, negative regulation of calcium ion transmembrane transporter activity, amine metabolic process, defense response to Gram-negative bacterium, and regulation of voltage-gated calcium channel activity-processes involved in neuroendocrine function, neuroplasticity, neurotransmission, and the immune-inflammatory system, all of which are closely associated with the mechanisms of depression. Moreover, light perception

and xenobiotic metabolism were observed in processes, suggesting that high-fat diets may impact environmental adaptability and metabolic detoxification functions. At the cellular component level, significant enrichment was noted for the ESCRT I complex, messenger ribonucleoprotein complex, atrophin-related glycoprotein complex, and glycoprotein complex. In the molecular functions, monoamine transmembrane transport activity was markedly enriched, supporting the hypothesis that 'a high-fat diet may induce depression by inhibiting monoamine neurotransmitter transport and disrupting associated signalling pathways'. Furthermore, we found oxidoreductase activity and organic acid transmembrane transport activity, further linking these processes to the pathological mechanisms of depression. Overall, A high-fat diet may impair neural function and homeostasis regulation by suppressing the expression of genes associated with calcium ion and monoamine neurotransmitter transport, thereby ultimately promoting the development of depression.

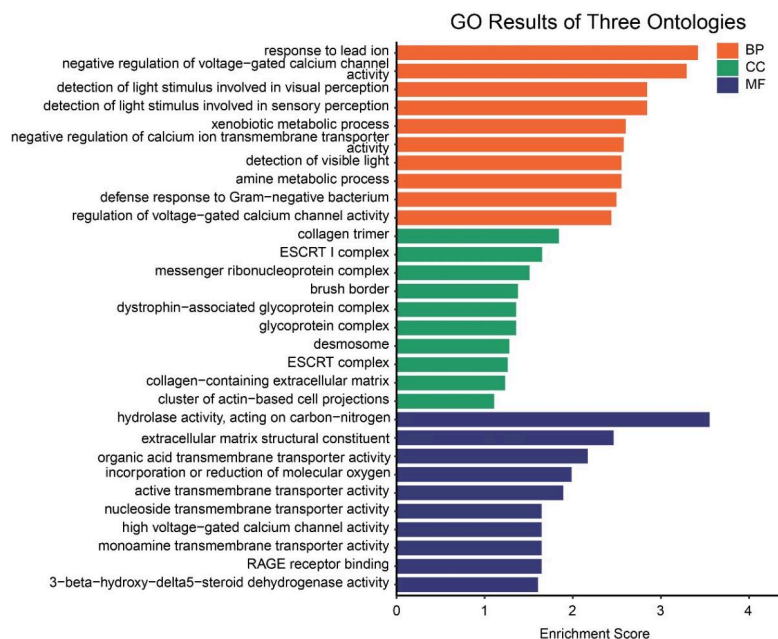

Figure 2. GO enrichment analysis of downregulated genes between the HFD and CD groups under stress

3.3. HFD mainly upregulated the genes involved in neurotransmitter receptor binding and neuronal signaling pathways

GO enrichment analysis of upregulated genes revealed significant enrichment (Fig. 3). In the biological process (BP) category, the phospholipase C-activating G protein-coupled receptor signaling pathway was significantly enriched and stood out. Meanwhile, regulation of pH, inorganic cation import / inorganic ion import / monovalent cation homeostasis, rho protein signal transduction, and positive regulation of angiogenesis were also significantly enriched. Cellular components were enriched in mitochondrial nucleoid, dynein complex, basal plasma membrane/basolateral plasma membrane, indicating associations with membrane-related functions. Molecular functions were significantly enriched in binding activities related to glutamate, D1 dopamine receptors, serotonin, acetylcholine, and other amine compounds, suggesting that HFD substantially affects multiple neurotransmitter systems.

Combined with the observed inhibition of monoamine transporter functions in downregulated genes, we hypothesize that HFD may induce a low-clearance, high-sensitivity neural state: the

downregulation of monoamine transporters might represent a compensatory mechanism to reduce neurotransmitter reuptake, while the upregulation of multiple neurotransmitter receptors may reflect enhanced neuronal sensitivity in response to diminished signaling. However, prolonged overactivation of glutamate and acetylcholine systems could disrupt neural circuit balance, potentially triggering or exacerbating depression-related symptoms such as anxiety, anhedonia, and cognitive impairment, ultimately leading to compensatory failure.

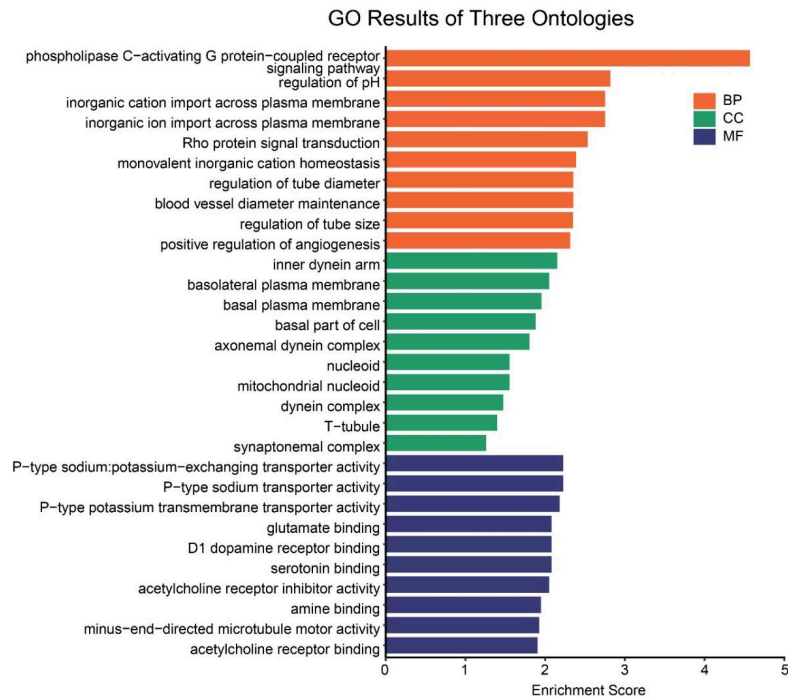

Figure 3. GO enrichment analysis of upregulated genes between the HFD and CD groups

3.4. The different expression genes are involved in neurotransmitter signaling, metabolic regulation, and neuroendocrine pathways

KEGG enrichment analysis revealed that down-regulated genes were significantly enriched in drug metabolism (CYP450), steroid hormone biosynthesis, protein digestion and absorption, as well as cortisol synthesis and secretion pathways ($p < 0.05$) (Fig. 4A); up-regulated genes were enriched in neuroactive ligand-receptor interaction, calcium signaling pathway, hormone signaling, alanine, aspartate and glutamate metabolism, renin-angiotensin system, and arginine biosynthesis, all of which are closely associated with depression (Fig. 4B). These results are highly consistent with the GO analysis, indicating that HFD may disrupt brain homeostasis through multi-system coordination (neurotransmitters, calcium signaling, metabolism, endocrine, etc.). The core mechanism might involve impaired neurotransmitter clearance, compensatory receptor hypersensitivity, and reduced metabolic and stress regulatory capacity, collectively promoting the development of depression.

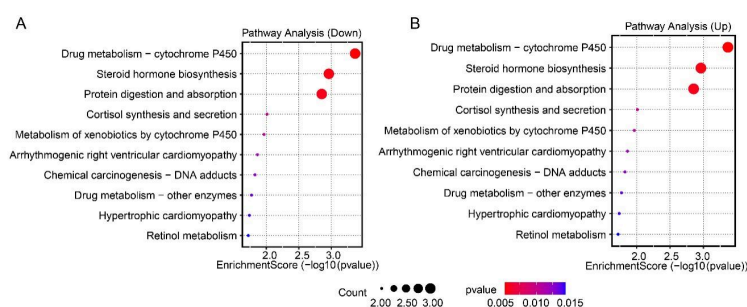

Figure 4. KEGG enrichment analysis was performed to identify significantly enriched pathways for downregulated (A) and upregulated (B) genes differentially expressed between the HFD and CD groups

3.5. Drug combination schemes targeting HFD-related depression selected using MFH

Dietary habits do indeed influence depression. In traditional Chinese medicine theory, the concept of “Medicine and Food Homology (MFH)” posits that many substances possess dual functions as both food and medicine, capable of providing nutrition while also treating illness.

Based on clinical guidelines for the diagnosis and treatment of depression in both traditional Chinese medicine and Western medicine, some formulations can shorten the course of antidepressant medication and reduce side effects. We summarized the composition of these Chinese patent medicines as follows:

Bupleurum, White Peony Root, Angelica Root, Poria, Atractylodes, Fried Licorice Root (or Licorice Root), Mint, Ginger, Cyperus Rhizome, Tangerine Peel, Ligusticum Root, Bitter Orange Peel, Moutan Bark, Gardenia Fruit, Curcuma Rhizome. According to China's latest list of food and drug substances (totalling 106 items), the following drugs are classified as MFH: Angelicae Sinensis Radix, Poria cocos, Glycyrrhiza uralensis, Mentha haplocalyx, Gardenia jasminoides, Zingiber officinale. In summary, we have identified six MFH substances with potential antidepressant effects: Angelicae Sinensis Radix, Poria cocos, Glycyrrhiza uralensis, Mentha haplocalyx, Gardenia jasminoides, and Zingiber officinale.

3.6. Network pharmacology analysis

3.6.1. Screening of potential targets for the anti-depression effects of MFH

Using the TCMSP and HERB databases, we predicted potential target sites for six food-medicine dual-use substances in MFH. After removing duplicate targets, we identified 262 MFH-specific potential targets and obtained Depression-related targets under stress (421 genes) and non-stress (770 genes) conditions from the DEG database. We found the same targets from MFH-predicted and depression-associated through Venn diagram analysis. The 13 common targets are potential mediators of catechin's antidepressant effects (Figure 5).

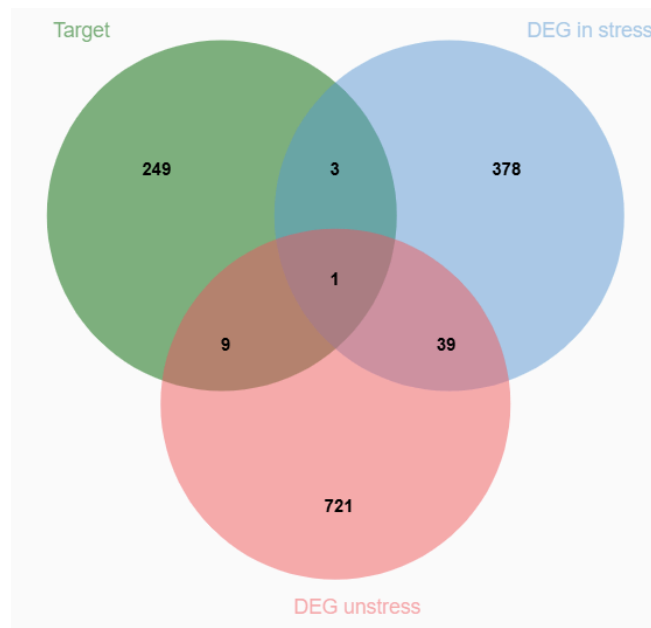

Figure 5. Venn diagram illustrating the overlap between MFH-predicted targets and depression-associated targets

We set up a protein-protein interaction (PPI) network for the 13 overlapping targets using the STRING database (Figure 6). There are 13 nodes and 10 connecting lines in the net. MMP9, ER α 1, and Cyp1b1 exhibit the highest connectivity (4, 4, and 3 connections, respectively), indicating that they may function as hub genes and key regulatory factors within this network.

Figure 6. PPI network of the overlapping targets

3.6.2. GO enrichment analysis of the potential targets

GO enrichment analysis of the 13 identified genes revealed significant enrichment ($p < 0.05$) (Figs. 7). Among biological processes, sodium ion transport emerged as the top enriched term, highlighting

its prominent role (Fig. 7A). Enriched cellular components were predominantly associated with membrane microdomains, including membrane rafts, the apical part of the cell, and presynaptic regions, suggesting involvement in membrane-related organization and neural signal transduction (Fig. 7B). Molecular function analysis showed significant enrichment in transporter activities, particularly active transmembrane transporter activity and active ion transmembrane transporter activity (Fig. 7C). These findings indicate that MFH may exert its effects on depression primarily by modulating neural signaling through the regulation of transmembrane ion transport and maintenance of ion homeostasis.

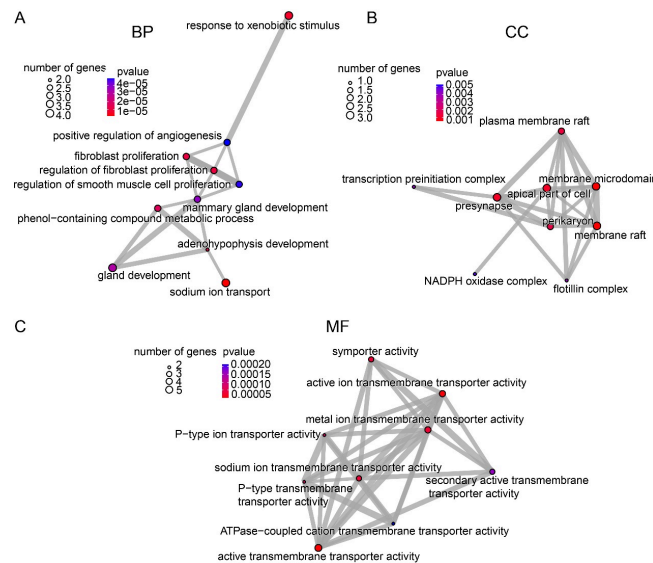

Figure 7. GO enrichment analysis of the key targets revealed significant (A) BP terms, (B) CC terms, and (C)MF terms

4. Discussion

Under stress conditions, HFD primarily affects the process or biological function of monoamine neurotransmitter transport and imbalance in glutamate and acetylcholine system activities, suggesting that HFD may promote the development of depression through potential targets such as monoamine transporters and multiple neurotransmitter receptors. Through network pharmacology analysis, we identified six food-medicine homologous substances with potential therapeutic effects against depression, whose mechanism may involve modulating the activity of membrane transporters, thereby influencing neural signalling and maintenance of ion homeostasis.

This study innovatively utilised GEO database analysis to examine the effects of a high-fat diet (HFD) on mouse brain transcriptional profiles under both stressed and unstressed conditions. Through differential gene expression and enrichment analysis, it was discovered that the HFD disrupts brain homeostasis via multi-system synergistic actions (involving neurotransmitters, calcium signalling, metabolism, endocrine systems, etc.). HFD may disrupt brain homeostasis through multi-system coordination (neurotransmitters, calcium signalling, metabolism, endocrine, etc.). The core mechanism might involve impaired neurotransmitter clearance, compensatory receptor hypersensitivity, and reduced metabolic and stress regulatory capacity, collectively promoting the development of depression.

Subsequently, another innovative approach was taken by focusing on substances with MFH using network pharmacology. Based on integrated Chinese and Western medicine guidelines for

depression diagnosis and treatment, practical components against high-fat diet (HFD)-induced depression were screened. We use the TCMSP and HERB databases to predict the action targets of six active herbal constituents in MFH, revealing potential multi-target mechanisms that contribute to its therapeutic effects on depression. MFH may be incorporated into food products, and also enhances therapeutic efficacy and reduces adverse reactions during pharmaceutical treatments. They may also serve as adjunctive therapies to calm the mind, replenish vital energy, and enhance cognitive function.

Of course, there are limitations. Our analysis is based on RNA-seq data from animal models, which cannot fully capture the complexity of human depression. Gene expression changes also do not necessarily prove causality; further experiments are needed to test these mechanisms directly. Moreover, diet-induced depression is shaped by many factors—including genetics, gut–brain communication, and lifestyle—which were not addressed in this study. Future research should integrate multiple “omics” approaches and, ideally, human data to give us a more precise and more complete picture.

In short, this work supports the idea that what we eat can profoundly shape brain health. A high-fat diet not only affects weight and metabolism—it also changes inflammatory and metabolic pathways in the brain that regulate mood. By uncovering these molecular patterns, we lay the groundwork for new strategies that integrate nutritional, metabolic, and psychiatric approaches to more effectively prevent and treat depression.
